LOCALIZATION OF RADIO-FREQUENCY TRANSCEIVERS

FIELD OF THE INVENTION

The present invention generally relates to a communication method and a system between a central server and mobile transceivers, called hereafter "stations", through a radio-frequency (RF) wireless network. More particularly, the invention relates to such a system able to work indoors or in public places.

BACKGROUND

In an indoor or public space environment, there is a need for a communication system able to dedicate applications (for example, access to specific services) on the basis of the location of a user (more precisely, a user station). A problem is to localize the stations in the environments with respect to physical areas to which dedicated proximity based application(s) are related.

Many outdoor localization techniques are known. For example, the GPS (Global Positioning System), the triangulation from earth fixed transceivers, the radio angle measurements, are efficient outdoor localization systems. However, such systems are unable to perform an indoor (in-building) localization due to the shielding resulting from walls and radioelements. Such

perturbing elements that can also be present outside render the above systems not very precise even outdoors.

A first known indoor localization system uses fixed infrared transceivers located in a building. The system determines in the field of which transceiver is the object and considers this field area as the location. A drawback of such a system is that many infrared fixed transceivers have to be installed in the building due to the poor range of IR access points, and their limitations to being line-of-site. Further, such a system has to be dedicated to the localization. Additionally, the data carrier bandwidth of IR-systems is not sufficient for most of the applications of wireless system for which the required transmission rate becomes higher and higher.

Recent indoor communication systems use radiofrequency transmission. Such systems provide fixed access points to the wireless communication network, which are distributed inside the building or public space to be covered. A station is connected to the network through the access point from which it receives the higher signal strength. This determination is made by the station itself which examines the signal levels received from the different access points, and then chooses one of these to communicate with to access network resources. The network routing protocol takes into account the access point choice of the station in order to switch the communication to the right access point. Of course, such systems also work outdoors, and at least a part of the access points can be located outdoors. For example, networks in accordance with the standard 802.11b to which the present invention applies more particularly belong to this type of systems.

Recently, some of these systems have been provided with a localization function of the stations, that is a determination of the physical location (and not only the determination of the access point to be connected to).

An example of such in-building radio-frequency wireless network system is described in the article "A Software System for Locating Mobile Users: Design, Evaluation, and

Lessons" by Paramvir Bahl, Venkata N. Padmanabhan and Anand Balachandran, published in December 2000, published at <http://www.cs.ucsd.edu/users/abalacha/research/papers/msr-tr-2000-12.pdf> as of November 2001. In that system, a history-based station-tracking algorithm takes into account the motion of the user station in order to follow this motion from an access point to another using a pre-determined and configured database representing a static signal strength map in principle.

Another example is described in the article "Determining User Location for Context Aware Computing Through the Use of a Wireless LAN Infrastructure" by Jason Small, Asim Smailagic and Daniel P. Siewiorek, published in December 2000, published on <http://www-2.cs.cmu.edu/~aura/publications.html>. Such a system uses a triangulation technique based on signal intensity from wireless access points.

A purpose of the present invention is to provide another localization method and system.

Another purpose of the present invention is to provide such a localization method and system particularly adapted to dedicate application(s) to the relative location of the stations.

Another purpose of the present invention is to provide such a method and system which do not need structural hardware modification of the existing mobile stations, wireless access points and central server.

Another purpose of the present invention is to provide a communication method and system between mobile stations and at least one central server through a radio-frequency wireless network, using proximity based applications.

Another purpose of the present invention is to provide a method and system adapted to omnidirectional RF system and, more particularly, to a wireless local area network of the standard 802.11b.

SUMMARY OF THE INVENTION

To attain these purposes and others, the present invention provides measuring the strengths or levels of the

signal received from a plurality of access points, by a mobile station to be located, storing the measured values with identifying physical addresses of the corresponding access points, and matching the stored values with signal strength thresholds of a
 5 table of event zones delimited by at least a signal strength boundary around an access point.

According to the present invention, an event zone corresponds to one or more attenuation ranges delimited by signal strength boundary(ies) around at least one access point.
 10 One or more event zones are defined in the wireless network environment depending on the physical location of the access points.

A feature of the present invention is to use, for the access points of a local area network, preferably of the 802.11b
 15 standard, signal strength attenuation thresholds to define, around the access points, attenuation ranges which are parts of event zones, and to use these virtual ranges to determine in which event zone(s) a mobile station communicating with one of the access points is located.

20 Applied to an indoor environment, the invention takes benefit of the fact that, even if a wall or similar RF affector constitutes a partial screen for the RF-field of an access point, it is not a drawback for the invention. Indeed, in an indoor environment, the event zone boundaries will often corre-
 25 spond to the wall of the building or of the rooms - depending on the variable adjustable attenuation range threshold(s) that are included in the definition of the event zone(s). Therefore, the
 -----attenuation of the wall contributes to the definition of the
 -----event zones.

30 According to the present invention, the communication link itself is not modified. For example, applied to a system
 -----selecting the access point from which the mobile station
 -----receives the highest signal strength, the communication is
 -----according to the invention still made through that way, inde-
 35 -----pendently from the determination of the event zone(s) to which
 -----the station belongs.

Another feature of the present invention is to launch or trigger applications or services based on the event zone(s) in which a given mobile station is located. In other words, having determined one or more event zones in which is located a station, a particular communication, which depends on the event zone(s) is established between that station and a central server.

As for the communication link itself, the location of a given mobile station with respect to the event zone(s) is periodically checked in order to update the proximity based applications if necessary.

BRIEF DESCRIPTION OF THE DRAWINGS

The foregoing and others purposes, features, aspects and advantages of the invention will become apparent from the following detailed description of embodiments, given by way of illustration and not limitation with reference to the accompanying drawings.

Figure 1 is a schematic representation of the main elements of a communication system to which the present invention applies;

Figure 2 illustrates coverage areas and attenuation ranges of defined event zones according to an embodiment of the present invention;

Figure 3 is a schematic representation of an indoor environment in which is implemented an embodiment of the present invention; and

Figure 4 is a flow chart of an implementation of the localization method according to the present invention.

For clarity, only the basic steps and elements that are necessary to the understanding of the present invention have been shown in the drawings and details will be described hereafter. In particular, the implementation of the invention by means of computerized systems will not be detailed as being in the ability of one skilled in the art. Further, the features of a local area network corresponding to the 802.11b standard will not be detailed as being well known by those skilled in the art.

DETAILED DESCRIPTION OF THE INVENTION

Figure 1 schematically represents the main components of a communication system to which the present invention applies.

5 A central server (CS) 1 is made, for example, of a network computer or any conventional computerized system, able to organize and control network communications, preferably according to the 802.11b standard. The central server 1 is generally connected to a wired network (not shown). Mobile
10 devices (MS) 2, called stations (for example Personal Computers or Personal Digital Assistants equipped with wireless network interface cards, or phones with 802.11b dual chipsets), provided with RF transceivers (symbolized by antennas 21), can communicate with the central server 1 through access points (AP) 3. The
15 access points 3 are wired to the central server (wires 4) and provided with RF transmitting means (symbolized by antennas 31). Access points act as interfaces between the server and the stations, i.e. the wireless and wired networks. Other stations (not shown) are usually wire connected to the central server.

20 However, the invention more particularly applies to wireless mobile stations. In Fig 1, a database (DB) 5 is connected to the central server. Database 5 aims at containing conventional data and programs, or retrieves data and programs or services via a network, and correspondence tables between the signal level
25 thresholds associated to each access point and the corresponding event zones of the environment to be covered by the system according to the invention.

~~The access points are distributed according to the environment to be covered. In the preferred application of the~~
30 ~~invention, the environment is, at least partially, indoor.~~

~~As in a conventional wireless network according to the 802.11b standard, a mobile station wanting to establish a communication with the central server selects, among the access points, the one from which it receives the highest signal strength or level. Each access point has an access point address, which is unique in the environment. A station wishing~~
35

to establish a communication compares the received signal strengths of the multiple access points it can see. The station then registers the access point that has the strongest received signal strength and uses that access point as its connection to the central server. The central server then uses the corresponding access point to exchange data with the station. Each access point has a unique identifying address (called its MAC address which is defined by the IEEE and controlled to be unique globally). The station communicates the MAC address of its current connected access point to the central server to be used for the localization, event zone identification, and application association for that station in that attenuation area in that event zone.

According to the invention, the signal strength data concerning a given station are used, on the central server side, to determine the location of the station with respect to event zones. Event zones are, according to the invention, fuzzy physical areas in each of which one or more access points of the networks can transmit and to which are associated one or more applications. An application is, according to the invention, service, software or data, which is available to a station located in the corresponding event zone.

According to the present invention, at least one specific application is dedicated to each event zone defined in the corresponding environment. The specific application can be data communicated to the mobile station(s) in the zones, programs stored in the central server or network which are executed for the mobile stations located in a given event zone, or services rendered available for the mobile stations located in the corresponding event zone(s).

For example, in a bank building in which event zones corresponding to bank services are delimited, an account consulting event zone can be defined in a physical area of the bank. When a user and its mobile station (for example, his personal digital assistant) comes into that area, the central server communicates to the station the balance of the bank

account of the user. Another event zone can be a stock exchange ordering zone in which the user can be connected to the order office of the bank. Out of the corresponding zone, the functionality is not available to the station.

5 Figure 2 schematically illustrates an embodiment of the localization and communication methods according to the present invention. These methods are, for example, implemented in a communication system as illustrated in figure 1.

10 According to the invention, the event zones are based on the signal attenuation around several access points. In other words, an event zone is limited by a virtual boundary of signal strength around one or several access points. For example, a first event zone EVA comprises the physical area corresponding to field areas of three access points AP1, AP2, AP3 for which
15 the attenuation of the signal is, respectively, lower than -32 dB, -40 dB and -48 dB. In figure 2, the attenuation ranges have been shown in full lines, and the event zone EVA has been delimited with long portions dotted line. A second event zone EVB is shown (in short portions dotted line) and comprises the
20 attenuation ranges lower than -48 dB of the access point AP3 and of a fourth access point AP4. The attenuation ranges used by the invention to define an event zone can or not be the same in terms of attenuation, for each access point of that zone.

25 For clarity, the areas have been shown approximately circular in Figure 2. However, and as it will be better understood in connection with Fig 3, these areas may have other shapes.

~~Figure 3 schematically represents an indoor environment to which the present invention applies.~~

30 In figure 3, four rooms R1, R2, R3, R4 and one corridor C of a building have been shown. Access points AP10-AP19 are distributed in the indoor environment. The access points are, for example, distributed into the indoor environment so as to give the ability to the central server to be connected to any
35 mobile station coming into the environment.

According to the present invention, the signal level thresholds used as boundaries of the attenuation ranges of the access points to define the event zones are fixed on the basis of the environment. In other words, knowing the physical map of the environment and the event zones to be created, the system is configured to define the level thresholds of the various access points.

For example, four event zones EV1-EV4 are defined in the environment of figure 3. These event zones approximately correspond to the different rooms as follows:

Event zone EV1: attenuation ranges around access points AP11, AP15 and AP16 with level thresholds chosen to correspond to rooms R1 and R4;

Event zone EV2: attenuation range around access point AP12 with level threshold chosen to correspond to rooms R2;

Event zone EV3: attenuation ranges around access points AP13 and AP14 with level thresholds chosen to correspond to rooms R3; and

Event zone EV4: attenuation ranges around access points AP17, AP18 and AP19 with level thresholds chosen to correspond to corridor C.

It should be noted that, for the implementation of the invention, the variations of the signal strength boundaries around an access point due to modifications of the environment (number of stations in the field of the access points, number of human bodies, humidity, etc.) can be compensated by providing overlapping attenuation ranges of the access points defining each event zone. Then, even if the attenuation range of a given access point becomes smaller, a station can still be localized in the event zone because it is in the field of another attenuation range.

Figure 4 is a simplified flowchart of the communication method according to the present invention.

The flowchart of figure 4 illustrates a loop for the localization and the access point selection. Preferably, these two determinations are made with the same periodicity (in the

same loop). According to this example, the first step (block 10, AP MAX SL) consists in establishing a communication between the station and the central server, in a conventional way, through the access point from which the station receives the highest signal level. According to the invention, the signal level values are stored dynamically only during the loop (block 11, SL TABLE) by the station with the identifying addresses of the corresponding access point it is connected to. Then (block 12, EZ CHECK), the received signal level measurement of the access point being used is compared to the predetermined threshold value(s) stored in a dedicated table to define the event zones. These comparisons lead to the localization of the station in term of event zone(s) in which the station is present. If the event zone is the same as in the preceding loop, the processing returns to block 10 for the next periodical check. If the event zone is not the same as in the preceding loop, the station is affected to a new event zone (block 13, NEW EZ) and the corresponding event (application) starts. Or if the station is not in a defined event zone, a pre-determined application or information is affected to the station.

According to a first embodiment of the present invention, a mobile station periodically checks the signal levels received from the various access points, and stores in a table the received signal level measurements and the corresponding access point address. Then, the obtained data of access point address and reception levels is transmitted to the central server. The server compares the measured levels with the thresholds stored in a table of definition of the event zones and comprising at least, for each event zone, the access point addresses of that zone and the corresponding signal strength threshold(s). If at least one of the strength measurements is lower than one configured threshold value, the station is considered located in the corresponding event zone. The station is identified with its address (IP address) which is unqualified on the network and dedicated to the physical corresponding

object (the PC, the mobile phone, the Personal Digital Assistant, etc.).

Alternatively or in combination, according to the invention:

5 an event zone can include one or more access point attenuation ranges;

 an access point can be included in more than one event zone;

10 the attenuation thresholds defining the attenuation ranges of several access points participating to a same event zone can be different from each other;

 the attenuation thresholds defining the attenuation ranges of an access point participating to several event zones can be different from one event zone to another (for example, 15 event zone EVB of figure 2 can be delimited with a coverage area of access point AP3 higher or lower (in term of attenuation) than -48dB);

 an event zone can be discontinuous, that is defined by non-overlapping coverage areas;

20 an event zone can be defined with more than one level threshold of a same access point (for example, an event zone can be delimited by two thresholds to define a ring around an access point);

 the event zone in which is located a mobile station is 25 independent to the access point through which this mobile station communicates with the central server. In some cases, a mobile station can communicate through an access point which does not serve to define the event zone in which the station is located; and

30 only a part of the access points of the environment can be used to define the event zone(s).

 An advantage of the present invention is to localize a mobile station not only with respect to the access points with which it communicates.

35 Another advantage of the invention is that the event zones are not physically fixed but can be modified as needed or

CLAIMS

1. A localization method of a mobile station (2) communicating with at least one central server (1) through a wireless network comprising a plurality of wireless radio-frequency transmitting access points (3), among which a first
5 access point is chosen to perform the communication, comprising the steps of:

measuring the signal strengths received by said station from the plurality of access points;

10 storing each measured strength with an address identifying the corresponding connected access point;

comparing said stored strengths to values of a predetermined table of signal strength thresholds affected to access points, defining one or more event zones (EZ) each comprising one or more attenuation ranges of one or more access points; and

15 considering the station as located in a given event zone if the measured strength corresponding to an access point defining that event zone is comprised in the attenuation range of that access point.

2. The localization method of claim 1, in which said
20 attenuation ranges are a function of the environment and of the shape of the event zones (EZ).

3. A communication method between at least one mobile station (2) and at least one central server (1) through radio-frequency transmitting access points (3) to which said station
25 is wireless connectable, comprising the steps of:

establishing a communication between said station and said central server through a first of said access points from which said station receives the highest signal strength;

30 comparing the signal strength received by said station from at least one second access point with respect to at least one signal strength threshold used for defining at least one event zone (EZ) in which at least one specific application of the server is to be available if said station is present in said event zone; and

making available for said mobile station said specific application if the station is considered in the event zone.

4. The method of claim 3, in which said station is considered to be in the event zone if the received signal strength is lower than said threshold.

5. The method of claim 3, in which said station is considered to be in the event zone if the received signal strength is higher than said threshold.

6. The method of claim 3, in which the station is considered as being in the event zone by applying the localization method of claim 1 or 2.

7. The method of claim 3, in which the communication are made according to the 802.11b standard.

8. A communication system between at least one mobile station (2) and at least one central server (1) through radio-frequency transmitting access points (3) to which the station is wireless connectable, comprising:

means to define, with at least a signal strength threshold of at least one access point, at least one event zone (EZ) in which at least one specific application of the server is to be available to the station if present in that zone;

means to localize the mobile station with respect to the event zone boundary, based on the signal strength received by the station from the access points.

9. The system of claim 8, in which the localization of the mobile station is performed by said central server (1) on the basis of a table defining each event zone (EZ) by attenuation-range(s)-around-one-or-more-access-points-(3)..

10. The system of claim 8, further comprising means to implement the communication method of any of claim 3 to 7.

LOCALIZATION OF RADIO-FREQUENCY TRANSCEIVERS

Abstract

The invention concerns a localization and communication methods and system between mobile stations and a central server through a wireless network comprising a plurality of wireless radio-frequency transmitting access points (AP1-AP4), among which a first access point is chosen to perform the communication, comprising the steps of measuring the signal strengths received by said station from the plurality of access points; storing each measured strength with an address identifying the corresponding connected access point; comparing said stored strengths to values of a predetermined table of signal strength thresholds affected to access points, defining one or more event zones (EVA, EVB) each comprising one or more attenuation ranges of one or more access points; and considering the station as located in a given event zone if the measured strength corresponding to an access point defining that event zone is comprised in the attenuation range of that access point.
